

35 % decreased (Delarue *et al.* 1996). In patients with type 2 diabetes, fish-oil supplementation does not ameliorate either hepatic or peripheral insulin resistance (Borkman *et al.* 1989). Thus, a discrepancy exists between observations in rats and in human subjects.

Exercise both prevents and reverses insulin resistance in human subjects (Henriksen, 2002) and in rats fed a high-fat diet (Kim *et al.* 2000). Such an effect involves glucose transport and insulin signalling in muscle (Henriksen, 2002). During a single bout of exercise of high intensity (65 % maximal O_2 consumption; VO_{2max}) performed by healthy subjects, both plasma glucose utilisation and HGP are strongly stimulated (Trimmer *et al.* 2002). The increase in HGP compensates for the increase in plasma glucose demand of working muscles, which prevents hypoglycaemia. In parallel, both CHO and fat oxidations are stimulated in response to the increased energy demand of working muscles (Romijn *et al.* 1993; Trimmer *et al.* 2002). Training alters fuel selection during exercise by inducing an increase in the stimulation of lipid oxidation and a reduction of the stimulation of CHO oxidation (Coggan *et al.* 1990). This alteration of fuel selection is associated with a parallel reduction of the stimulation of plasma glucose utilisation and HGP. The decrease in the stimulation of plasma glucose fluxes after training is attributed to the increased capacity of muscle to oxidise fat (Coggan *et al.* 1990).

As dietary fish-oil supplementation decreases the stimulation of CHO oxidation by 35 % and increases fat oxidation by 35 % during an oral glucose load in subjects at rest (Delarue *et al.* 1996), the present study tested the hypothesis that if fish oil alters fuel selection during exercise as it does at rest, plasma glucose fluxes could be reduced. For that purpose, untrained male subjects were studied during a cycle exercise maintained over 90 min at 60 % VO_{2max} before and after a 3-week dietary fish-oil supplementation.

Materials and methods

Subjects

Six active, but untrained, men (23 ± 1 years; 67.6 ± 2.7 kg) participated in the study. All subjects were in good health, non-smokers and were not taking any drugs or alcohol. None had a personal or family history of diabetes. Their usual energy intake was estimated from a 7 d dietary recall. They were asked to maintain their usual physical activity. Ethanol was excluded and coffee intake was restrained. Their VO_{2max} was obtained 15 d before the beginning of the study from a calibrated exercise on an ergometric cycle (2.9 (SE 0.2) litres/min for a power load of 225 (SE 13) W). The experimental protocol was approved by the Ethical Committee of Tours. Before participating in the study, each subject provided informed written consent.

Experimental design

The duration of the overall study was 40 d, including two consecutive 20 d periods. During the first period, subjects

ingested 6 g olive oil/d; during the second period, they ingested 6 g fish oil/d. Olive oil or fish oil was given as six capsules of 1 g each (two capsules at breakfast, two capsules at lunch and two capsules at dinner). The subjects were unaware of the type of oil contained in the capsules. The two periods with olive-oil or fish-oil supplementation were deliberately not randomised because *n*-3 long-chain fatty acids are incorporated into membranes whose composition remains altered at least 18 weeks after interruption of fish-oil supplementation (Endres *et al.* 1989). Thus, during such a prolonged period, other factors could have changed, which could have affected metabolic responses to exercise. By using olive oil during the first period, it cannot be excluded that monounsaturated fatty acids are incorporated into membranes. Strictly, the design of the present study leads to a comparison between olive oil and fish oil; olive oil cannot be considered as a 'placebo' of fish oil. During the two periods, the subjects were asked to maintain their usual physical activity. Each period included two consecutive phases; a first 15 d phase, during which subjects were asked to maintain their usual diet, was followed by a second 5 d phase, during which the diet was controlled. During this second 5 d phase, subjects ingested under supervision in our metabolic unit a maintenance iso-energetic diet containing 50 % CHO, 30 % fat and 20 % protein, partitioned into three meals. The energy requirements were estimated from resting metabolic rate (calculated according to Weinsier *et al.* 1992) and a physical factor activity (1.25 or 1.35) estimated from an interview. This value was then adjusted after comparison with the usual energy intake obtained from the subjects' dietary records. This method was chosen to avoid a significant error in the dietary record by using the 7 d recall, which is known to lack precision. The absence of variation of body weight during the study confirmed that this method was valid. Each meal was prepared individually from usual French food, cooked and weighed (± 1 g) by a dietitian. Blood samples were taken on the last day of each period for the determination of the fatty acid composition of plasma triacylglycerols.

Materials

Olive oil and fish oil were kindly provided by Groupe Danone (Le Plessis Robinson, France). The composition of these oils is reported in Table 1. $[6,6-^2H_2]$ glucose (99 mol % excess) and $[1,1,2,3,3-^2H_5]$ -glycerol (99 mol % excess) were purchased from Cambridge Isotopes Laboratory (Andover, MA, USA). Isotopic and chemical purity were checked by GC-MS (Hewlett-Packard 5971, series II; Hewlett-Packard, Les Ulis, France). Tracers were prepared as sterile pyrogen-free solutions in normal saline. The solutions were filtered through a $0.22 \mu m$ Millipore filter (Millipore Corp., Bedford, MA, USA) during priming and intravenous infusions.

Tests

Each subject was studied twice, once on day 20, then on day 40. The tests were conducted over 270 min, in the morning after a 12 h fast. After voiding, the subjects

were placed at rest in a bed for 180 min before performing a 90 min exercise on an ergometer cycle; the exercise was performed at the same absolute workload during the two tests, i.e. 60 % VO_2max determined before the study. One intravenous catheter was inserted into a wrist vein for the collection of blood samples. Another catheter was inserted into an antecubital vein of the contralateral arm for the infusion of tracers. The rate of plasma glucose disappearance (Rd glucose) and the rate of HGP were traced using $[6,6\text{-}^2\text{H}_2]\text{glucose}$. A prime-constant infusion of $[6,6\text{-}^2\text{H}_2]\text{glucose}$ (prime 16 $\mu\text{mol/kg}$ body weight, continuous 0.2 $\mu\text{mol/kg}$ per min) was started 180 min before the exercise period and maintained over 90 min. Then, in order to minimise the variations in isotopic enrichment in ^2H of plasma glucose, the infusion rate of $[6,6\text{-}^2\text{H}_2]\text{glucose}$ was increased step-by-step every 30 min during the exercise period. The infusion rates were ($\mu\text{mol/kg}$ per min): $T_{0-30\text{ min}}$, 0.4; $T_{30-60\text{ min}}$, 0.5; $T_{60-90\text{ min}}$, 0.6. Lipolysis was assessed by using a primed (1.5 $\mu\text{mol/min}$) continuous (0.1 $\mu\text{mol/kg}$ per min) infusion of $[1,1,2,3,3\text{-}^2\text{H}_5]\text{glycerol}$ started from $T_{-180\text{ min}}$ and maintained over 270 min.

From $T_{-60\text{ min}}$ to $T_{90\text{ min}}$, CO_2 and O_2 volumes were measured using an open-circuit indirect calorimeter with a ventilated hood as previously described (Delarue *et al.* 1994). Blood samples were collected every 15 min from $T_{-30\text{ min}}$ to $T_{90\text{ min}}$ for determinations of plasma glucose, non-esterified fatty acids, β -hydroxybutyrate, lactate, insulin and glucagon concentrations, and of plasma isotopic enrichment in ^2H of glucose and glycerol. Other blood samples were collected at 0, 60 and 90 min for determination of noradrenaline and adrenaline concentrations. Urine was collected from $T_{-180\text{ min}}$ to $T_{90\text{ min}}$ for determination of total N.

Sampling and analytical procedures

Blood samples were collected into heparinised tubes and were immediately spun at 4°C. Plasma was separated into portions and frozen at -80°C until the time of

assay. Urine samples were frozen at -80°C for further determination of total urinary N. Triacylglycerols from oils or plasma were separated and purified by using TLC on silica gel with hexane–diethyl ether–acetic acid (70:30:1, by vol.) as the developing solvent (Bligh & Dyer, 1959). Fatty acids were determined by direct methylation with boron trifluoride–methanol (90 min at 100°C), and spots were scraped from TLC plates. Methyl esters of fatty acids that were obtained were diluted in hexane before separation by GC. Plasma glucose concentrations were measured by the glucose oxidase method using a Beckman glucose analyser 2 (Beckman Instruments, Fullerton, CA, USA). Non-esterified fatty acid concentrations were measured by an enzymic colorimetric method with the use of a commercial kit (NEFA C; Wako Chemicals, Freiburg, Germany). Lactate and β -hydroxybutyrate concentrations were determined with standard enzymic methods (Bergmeyer *et al.* 1988). Plasma insulin (INS-IRMA; Biosource Europe S.A., Nivelles, Belgium) and glucagon concentrations were measured by a radioimmunoassay. Plasma catecholamines were determined by HPLC. Total urinary N was determined with the use of Kjeldahl's method (Hawk, 1947). The isotopic enrichment in ^2H of plasma glucose was measured by electron impact ionisation on the penta-acetate derivative of glucose and the selective monitoring of ions of m/z 200 and 202 by using GC–MS (Hewlett-Packard 5971; series II; Hewlett-Packard) as previously described (Delarue *et al.* 1996). The isotopic enrichment in ^2H of plasma glycerol was measured by electron impact ionisation on the glycerol 1,1,2,3,3 tri-acetate derivative and the selective monitoring of ions of m/z 145 and 148 by using GC–MS (Hewlett-Packard 5971, series II; Hewlett-Packard) as previously described by Beylot *et al.* (1987).

Calculations

The Rd glucose and HGP were calculated in the non-steady state using Steele's equation (Steele *et al.* 1956) as modified by De Bodo *et al.* (1963). The plasma glycerol rate of appearance was also calculated in the non-steady state by using the same equation (De Bodo *et al.* 1963). The glucose metabolic clearance rate was calculated as the Rd glucose/glycaemia.

Total CHO oxidation and total lipid oxidation were calculated from the volumes of CO_2 and O_2 and urinary N excretion using the equations of Livesey & Elia (1988). It was assumed that N excretion was the same at rest and during exercise.

Minimal muscle glycogen oxidation was calculated as total CHO oxidation minus Rd glucose (Romijn *et al.* 1993; Phillips *et al.* 1997) assuming that 100 % of the glucose that disappeared from the plasma was oxidised during exercise. This calculation would underestimate the minimal rate of glycogen oxidation when plasma glucose is converted directly to lactate or when it is converted into glycogen in muscle (Romijn *et al.* 1993).

The contribution of plasma glucose to total CHO oxidation was calculated as Rd glucose/total CHO oxidation.

Statistical methods

All data are expressed as mean values with their standard errors. Changes in measured or calculated parameters over time during each period were compared using a one-way ANOVA for repeated measures. Comparison of values between the two periods used a two-way ANOVA for repeated measures. When a significant interaction was found, a *post hoc* test was used to determine pairwise differences. The software used was Statview™ F (Abacus Concepts, Inc., Berkeley, CA, USA) running on a Powerbook G4 (Apple, Cupertino, CA, USA).

Results

Weight and dietary intakes

The weight of the subjects was similar at the end of the olive-oil and fish-oil periods (67.6 (SE 2.7) v. 67.7 (SE 2.6) kg respectively). Measured energy and macronutrient intakes during the 5 d controlled diet periods were similar between olive oil and fish oil (Table 2).

Fatty acid content of plasma triacylglycerols

The total *n*-3 fatty acid content of plasma triacylglycerols was higher after fish oil than after olive oil (6.5 (SE 0.5) v. 2.4 (SE 0.4) % respectively; $P < 0.0001$) (Table 3).

Metabolites and hormones

As compared with rest, glycaemia and insulinaemia decreased over time during exercise (both $P = 0.0001$; Figs. 1 and 2). Conversely, glucagonaemia increased over time during exercise ($P < 0.05$; Fig. 2). Lactataemia increased for 15 min, then decreased progressively before reaching a plateau at 60 min (Fig. 1; $P < 0.001$). Glycaemia, lactataemia, insulinaemia and glucagonaemia were similar between olive oil and fish oil at rest and during exercise. Glycerol was lower at rest and after 90 min of exercise with fish oil than with olive oil (both $P < 0.05$) (Table 4). Non-esterified fatty acids and β -hydroxybutyrate concentrations were higher at the end of exercise as compared with rest ($P < 0.05$) and not different between olive oil and fish oil (Table 4). Adrenaline and noradrenaline were lower in the basal state during fish-oil than during olive-oil supplementation ($P < 0.05$; Table 5). They increased during exercise and were not different between olive oil and fish oil (Table 5).

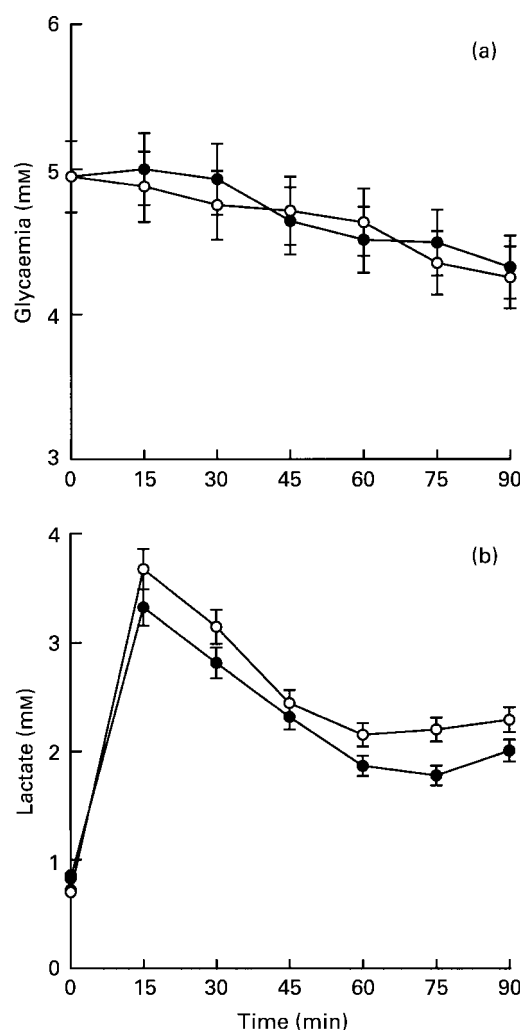

Fig. 1. Plasma glucose (a) and lactate (b) at rest and during cycling exercise (60% maximal O_2 consumption) after 20 d dietary olive-oil (○) or 20 d fish-oil (●) supplementation in six untrained male subjects. Values are means, with their standard errors represented by vertical bars.

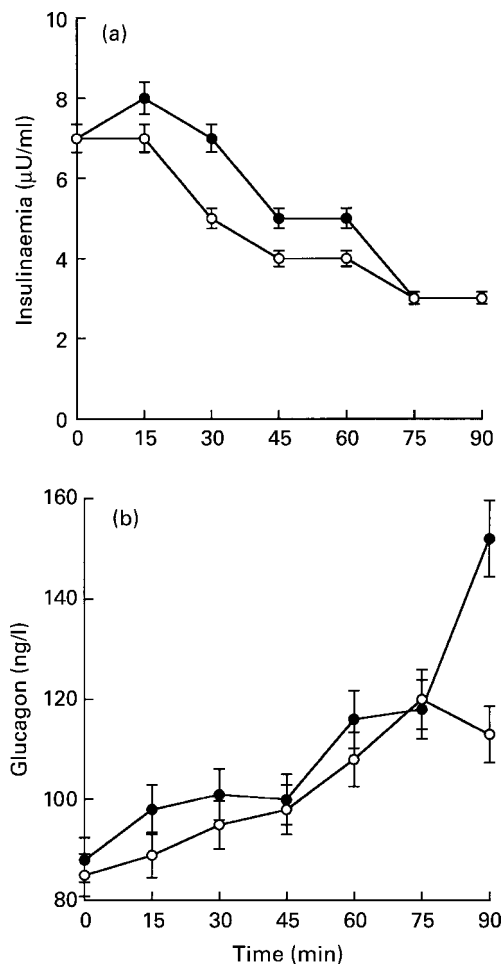

Fig. 2. Plasma insulin (a) and glucagon (b) at rest and during cycling exercise (60% maximal O_2 consumption) after 20 d dietary olive-oil (○) or 20 d fish-oil (●) supplementation in six untrained male subjects. Values are means, with their standard errors represented by vertical bars.

Plasma glucose fluxes

The Rd glucose increased continuously during exercise ($P=0.0001$; Fig. 3). The Rd glucose was less stimulated from $T_{60\text{ min}}$ to $T_{90\text{ min}}$ after fish oil than after olive oil ($P<0.05$). HGP increased in parallel with the Rd glucose ($P=0.0001$) and was less stimulated from $T_{60\text{ min}}$ to $T_{90\text{ min}}$ after fish oil than after olive oil ($P<0.05$; Fig. 3). The metabolic clearance rate of glucose increased during exercise ($P<0.001$) and was lower at $T_{75\text{ min}}$ and $T_{90\text{ min}}$ after fish oil than after olive oil (Fig. 3).

Plasma glycerol fluxes

The rates of glycerol appearance and disappearance (Fig. 4) increased continuously during exercise ($P<0.001$) and were not different between olive-oil and fish-oil periods.

Energy expenditure, substrates oxidation, and muscle glycogen oxidation

Energy expenditure increased steadily at $T_{15\text{ min}}$ then remained almost constant around 33 kJ/min until $T_{90\text{ min}}$

($P<0.001$) during both olive-oil or fish-oil periods (Table 6). Total fat oxidation increased regularly until $T_{90\text{ min}}$ ($P<0.001$) and tended (non-significantly) to be higher after fish oil than after olive oil (Table 6). Total CHO oxidation increased over time during exercise ($P<0.001$) and tended to be lower (non-significantly) after fish oil than after olive oil (Table 6). Muscle glycogen oxidation tended to be lower after fish oil than after olive oil (7.1 (SE 0.5) mg/kg per min at $T_{90\text{ min}}$ v. 8.3 (SE 1.25) mg/kg per min at $T_{90\text{ min}}$ respectively) but the difference did not reach statistical significance. The contribution of the plasma disappearance of glucose to total CHO oxidation was identical between olive oil and fish oil (Fig. 5).

Discussion

The main observation of the present study is that a supplementation of the usual diet with 6 g fish oil/d during a period of 3 weeks reduced the stimulation of both HGP (-21%) and the Rd glucose (-26%) during exercise. The reduction of the stimulation of the Rd glucose during exercise in the present study was due to a decrease in the metabolic clearance of glucose. This suggests an effect of *n-3* fatty acids at the level of non-insulin dependent glucose transport. Assuming that 100% of the glucose that disappeared from the plasma was oxidised, then plasma glucose oxidation was reduced by fish oil. Because the reduction of plasma glucose oxidation with fish oil represented only about 12% total CHO oxidation, the impact on total CHO oxidation was minimal. However, the observation that the contribution of the Rd glucose (plasma glucose oxidation) to total CHO oxidation was identical between olive oil and fish oil demonstrates that CHO oxidation from sources other than plasma glucose was also reduced in the same proportion. As expected, fat oxidation increased during exercise and tended to be higher after fish oil than after olive oil. When calculating the energy equivalent of the difference in fat oxidation between the olive-oil and fish-oil periods, it appears that there is compensation for the decrease in energy from CHO oxidation. Thus, it can be hypothesised that fish oil induced a slight alteration in fuel selection responsible for the decreased Rd glucose. The absence of a significant difference of whole-body substrates oxidation could be explained by the lower sensitivity of the measurement of substrates oxidation as compared with the measurement of plasma glucose fluxes. It is noteworthy that the alteration of fuel selection induced by fish oil during exercise was less marked than that induced during an oral load taken in the resting state (Delarue *et al.* 1996). During an oral glucose load, the alteration of fuel selection mainly depends on the effect of insulin whereas during exercise the alteration of fuel selection is mainly independent from insulin. Thus, it can be hypothesised that the effect of fish oil on fuel selection implicates mainly pathways activated by insulin. It is unlikely that fish oil altered the Rd glucose by a decreasing effect on glucose transport. Indeed, fish oil prevents the defect of muscle glucose transport during high-fat diet treatment in rats (Storlien *et al.* 1996) and does not alter the Rd glucose during an oral glucose load in spite of a 40% lower insulin response in healthy

human subjects (Delarue *et al.* 1996). In addition, if fish oil does not reverse peripheral insulin resistance in patients with type 2 diabetes, it does not reduce the Rd glucose during a hyperinsulinaemic clamp (Borkman *et al.* 1989; Rivellese *et al.* 1996). However, exercise stimulates glucose transport in muscle by inducing the recruitment of a specific pool of glucose transporters (GLUT) 4 different from that stimulated by insulin (Hayashi *et al.* 1997). Also, exercise induces hexokinase II activity strongly associated to GLUT4 (Koval *et al.* 1998), and so it might be possible that fish oil altered the pathway of translocation of this specific pool of GLUT4 and/or hexokinase II activity. It has been shown that long-chain PUFA decrease hexokinase activity in the heart (Stewart & Blakely, 2000), but no demonstration of such an effect in skeletal muscle has been reported. Recently, it has been suggested that glucose uptake during exercise could be driven by the activation of AMP-activated protein kinase (Winder *et al.* 1999). Whether fish oil could alter this pathway remains

to be studied. The subjects in the present study were tested twice at the same workload. A difference in O₂ consumption capacity is unlikely since fish oil does not modify VO₂max (Raastadt *et al.* 1997). An alteration of blood flow or its redistribution is also unlikely. Indeed, plasma catecholamines were similar between the two tests on one hand and eicosapentaenoic acid, a long-chain *n*-3 PUFA contained in fish oil, increases peripheral vasodilation, which should have increased the Rd glucose (Tagawa *et al.* 1999).

The reduction of HGP stimulation matched the reduction in the Rd glucose so that glycaemia was similar during exercise with olive as with fish oil. The parallel decrease in plasma glucose utilisation and in HGP implies a coordinate effect of fish oil on plasma glucose transport and on intrahepatic glucose metabolism. The decrease in stimulation of HGP with fish oil probably results from an adaptation to the decreased stimulation of the Rd glucose via feedback mechanisms involving the central nervous

Fig. 3. Hepatic glucose production (HGP) (a), rate of plasma glucose disappearance (Rd glucose) (b) and plasma glucose metabolic clearance rate (MCR) (c) at rest and during cycling exercise (60% maximal O_2 consumption) after 20 d dietary olive-oil (○) or 20 d fish-oil (●) supplementation in six untrained male subjects. Fig. 4. Rates of plasma glycerol appearance (Ra glucose) (a) and disappearance (Rd glucose) (b) at rest and during cycling exercise (60% maximal O_2 consumption) after 20 d dietary olive-oil (○) or 20 d fish-oil (●) supplementation in six untrained male subjects. Values are means, with their standard errors represented by vertical bars.

system or other modulators (Wasserman, 1995). In the present study, if such an adaptation occurred, it was unlikely due to a lower sympathetic activity because plasma catecholamines did not differ between fish-oil and olive-oil periods during exercise although they were lower after fish oil at rest. The mediators of such a feedback mechanism during exercise without or with fish oil have not yet been discovered. The effect of fish oil on HGP could have resulted from a decrease in gluconeogenesis and/or glycogenolysis on one hand and/or from a decrease in flux through G6Pase on the other hand. A decrease in stimulation of the gluconeogenesis rate is very unlikely considering that plasma lactate concentrations as well as the rates of glycerol appearance and disappearance were similar with or without fish oil. In addition, factors regulating the gluconeogenesis rate, i.e. the insulin:glucagon ratio and liver fatty acids oxidation (estimated by β -hydroxybutyrate concentrations) were similar between the two tests. A decrease in liver glycogenolysis cannot be ruled out. However, it should be noted that long-chain *n*-3 PUFA stimulate glycogen phosphorylase in hepatocytes (Gomez-Munoz *et al.* 1991), which does not plead for a

decrease in liver glycogenolysis in the present study. Finally, a decreased flux through G6Pase cannot be completely ruled out because long-chain *n*-3 PUFA have been demonstrated to decrease G6Pase expression and activity in rat liver (Danièle *et al.* 1997; Rajas *et al.* 2002).

Glycaemia decreased similarly during exercise in both experiments because glucose utilisation was slightly higher than hepatic glucose production. This phenomenon has been reported before (Trimmer *et al.* 2002) and confirms that the stimulation of HGP cannot compensate for the high rates of plasma glucose utilisation when liver glycogen content has been compromised by fasting and exercise.

The present study considered the possibility that the decreased plasma glucose fluxes observed after fish-oil supplementation might be due to an adaptation to physical exercise due to the repetition of the testing procedure over time. The non-random performance of exercise tests in the design of the study was used because of the long washout

period (18 weeks, i.e. 4.5 months) required for the complete disappearance of *n*-3 fatty acids in plasma membranes (Endres *et al.* 1989). Performing two tests after such a very long washout period entailed the important risk of a change in other factors, which could have confounding effects on the metabolic response to exercise. Such factors include intercurrent illness, change in dietary habit because of seasonal variation or holidays, and change in physical activity due possibly to holidays or other causes. Another risk was the possible dropout of subjects who might be less inclined to attend for the second test after a long wait. This lack of randomisation is very unlikely to explain the effect that was observed after fish oil because caution was taken to try to prevent as much as possible the contribution of confounding factors. Indeed, the subjects received olive-oil then fish-oil supplementation during the same length of time, i.e. 20 d each. The subjects' body weight was similar at the end of each period implying a similar energy balance during the two periods. The diet was strictly controlled during the last 5 d of each period as confirmed by the similar measured intakes. The resting values of substrates and hormones concentrations as well as of resting energy expenditure were not different in the morning of each of the two tests in accordance with a similar metabolic status. Moreover, a possible effect of the previous test on the second test was very unlikely because the time that elapsed between the two tests had a duration of 20 d. This period of time is sufficient to return to previous metabolic status; the exercise had a short duration (90 min) and was not repeated over many days so that a training effect was very unlikely to occur. The subjects were asked to maintain their usual physical activity during the two periods, which was obtained as confirmed by anamnesis. Green *et al.* (2000) observed that a single training session elicited metabolic adaptations similar to those reported after training of long duration. However, the type of training session performed by the subjects in the Green *et al.* (2000) study was very different from the exercise performed by the subjects in the present study. In the Green *et al.* (2000) study, the training session involved 6 min each hour at 90% VO₂max for 16 h and not continuous exercise over 90 min at 60% VO₂max. Last, as a part of another study (J Delarue *et al.* unpublished results), the subjects from the present study were studied 5 d after the first exercise of the present study, while absorbing over that 5 d a high-CHO diet. The Rd glucose and HGP were not different (data not shown) indicating that the reduction of plasma glucose fluxes was not modulated by repetition of exercise or the high-CHO diet, which reinforces the very possibility of a specific effect of fish oil. Thus, it can be said with confidence that in the present study, fish oil did reduce plasma glucose fluxes during exercise.

In summary, a 3-week fish-oil consumption in untrained subjects decreases the Rd glucose by 26% and HGP by 21% during 90 min cycling at 60% VO₂max, which could be related to a tendency to an increasing effect of fish oil on fat oxidation substituting for CHO oxidation. The parallel decrease of the Rd glucose and HGP is probably due to a feedback mechanism of adaptation of HGP to the decreased Rd glucose.

Acknowledgements

This work was supported by a grant from Groupe Danone. The authors thank Professor Luc Tappy (Lausanne) for his very helpful discussion of the results. The technical assistance of Mrs Objois was deeply appreciated.
